Abstract

A 83-year-old female patient suffered from acute kidney injury a month after percutaneous coronary intervention. Two weeks before hospitalization, she experienced nausea and intermittent watery diarrhea. Laboratory test showed high levels of serum creatine kinase and lactate dehydrogenase, which were remarkably decreased after ceasing rosuvastatin and valsartan treatment. Despite the recovery of renal function, unfortunately one week later, she was diagnosed with agranulocytosis because of antibiotic therapy. When we stopped meropenem and switched to granulocyte-colony stimulating factor treatment, her white blood cell count returned to a normal range. In our case, both rhabdomyolysis and agranulocytosis were induced by drugs. We provided a literature review of the causes of acute kidney injury and the pathogenesis of rhabdomyolysis and agranulocytosis. We discussed how drugs might lead to these complications. This case highlights the need to be aware of the potential side effects of drugs, especially those given to elderly patients who are likely to be receiving several medications concurrently for managing chronic diseases.

Keywords: Acute kidney injury; Rhabdomyolysis; Agranulocytosis

Introduction

Due to the increase in life expectancy, more geriatric patients are present in the hospital. They often have several chronic diseases and are taking numerous medicines at the same time. Drug induced acute kidney injury is very common, especially for the contrast-induced nephropathy after percutaneous coronary intervention and other interventional operations. Here, we report a case of acute kidney injury induced by rhabdomyolysis in an elderly patient who recently underwent a percutaneous coronary intervention. She also suffered from agranulocytosis induced by antibiotic drugs. We provide a literature review of the causes of acute kidney injury and the pathogenesis of

rhabdomyolysis and agranulocytosis. We hope that this case would raise the awareness of considering the potential side effects of drugs especially in geriatric patients. Many older adults have multiple medical conditions, such as hypertension, arthritis, heart disease, cancer, and diabetes mellitus, which require multiple medications for proper treatment [1]. A national survey found that 57% of US women aged ≥ 65 years took ≥ 5 prescription medications and 12% took ≥ 10 medications [2].

Case History

A 83-year-old female patient was admitted due to a continuous increase in serum creatinine (sCr) level peaked at 715 $\mu\text{mol/L}$. She has a past medical history of coronary heart disease and atrial fibrillation for over 10 years, taking amiodarone and betaloc to control ventricular rate. She also has a history of high blood pressure (maximum 180/100 mmHg) over 20 years, which is managed by valsartan 80 mg/d, furosemide 20 mg/d, and spironolactone 20 mg/d. One month before admission, this patient had undergone a coronary angiography and percutaneous coronary intervention (PCI) after presenting with chest tightness and chest pain. She routinely took clopidogrel 75 mg/d and aspirin 100 mg/d for preventing platelet aggregation and rosuvastatin 10 mg/d for plaque stabilization after PCI. Her sCr increased from 122 $\mu\text{mol/L}$ to 138 $\mu\text{mol/L}$ two days after operation. Two weeks later, she suffered from nausea and intermittent watery diarrhea. At the same time, she had soy urine without fever and muscle pain or swelling.

On the first day of hospitalization, her blood pressure was 90/61 mmHg; heart rate was 108 per minute with atrial fibrillation. Physical examination showed that her abdomen was flat, with no tenderness and rebound tenderness. No edema was observed in her lower limb. Laboratory blood test and urinalysis reported a sCr of 489 $\mu\text{mol/L}$, serum K^+ of 2.98 mmol/L, serum Ca^{2+} of 2.04 mmol/L, serum creatine kinase (CK) of 4621 U/L, serum lactate dehydrogenase (LDH) of 764 U/L, white blood cell (WBC) count of $5.4 \times 10^9/\text{L}$, neutrophil percentage (N%) of 83.4%, urine UBG (+/-), and urine ERY (+).

Abdominal ultrasonography revealed an enlargement of the gallbladder, cholecystitis, multiple gallbladder stones, and bile duct dilatation. Both kidneys were of normal size, but their structure appeared fuzzy.

In hospital, her blood pressure had once dropped to 50/30 mmHg, and her urine volume was only 200 mL in the first 24 h. We, therefore, administered colloidal solution (Albumin, Intralipid) to expand the blood volume and dopamine to increase the blood pressure. We stopped using rosuvastatin and valsartan. In addition, we started administering meropenem 1.0 g bid by intravenous infusion to treat potential infection, Caltrate D to regulate calcium phosphorus metabolism, potassium chloride to manage hypokalemia, and sodium bicarbonate to alkalinize urine. On the third day after admission, this patient entered a polyuria stage with her urine volume went up to 3.8 L/day, whereas the CK and LDH levels decreased remarkably (Figure 1). Her renal function also recovered gradually (Figure 2).

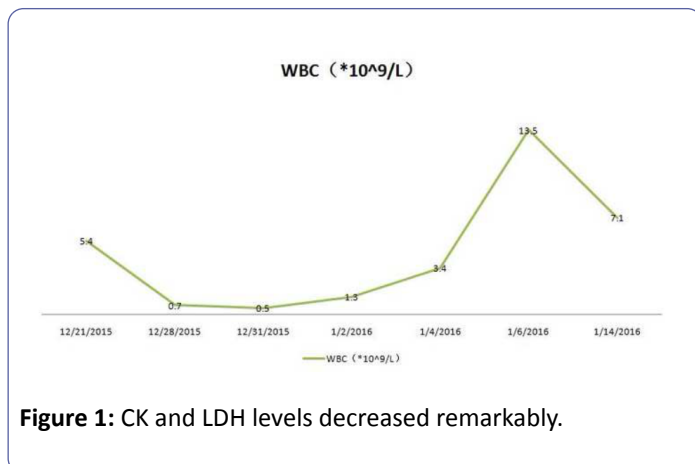

Figure 1: CK and LDH levels decreased remarkably.

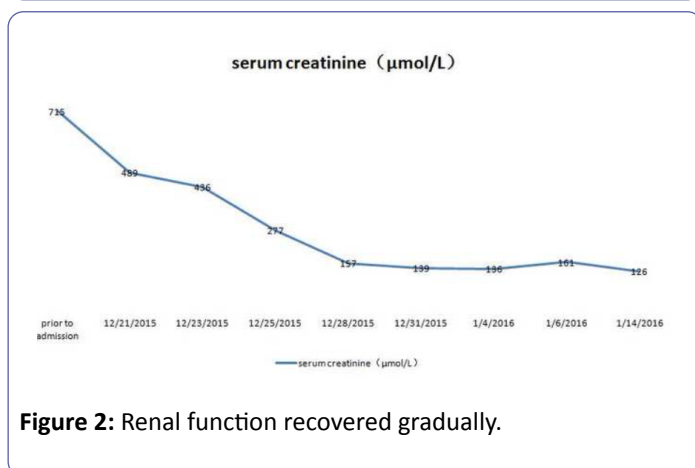

Figure 2: Renal function recovered gradually.

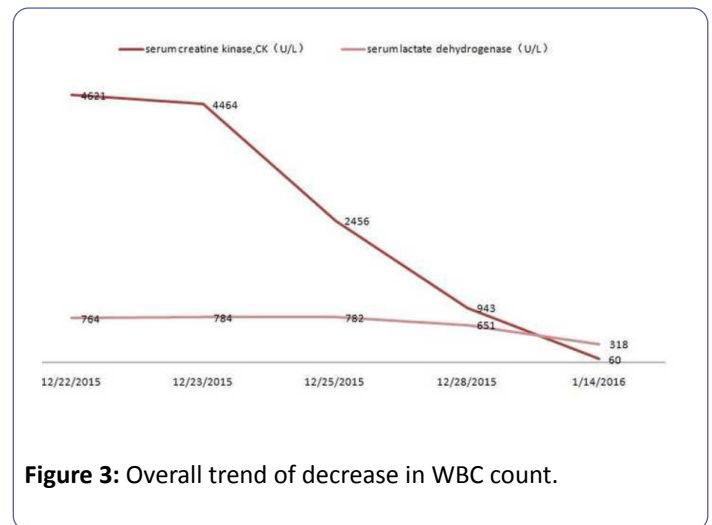

Figure 3: Overall trend of decrease in WBC count.

One week after admission, her blood report showed an overall trend of decrease in WBC count (Figure 3), indicative of an agranulocytosis that might be induced by meropenem intravenous infusion. Therefore, we immediately stopped meropenem and switched to granulocyte-colony stimulating factor (G-CSF) 100 u/d by hypodermic injection. One week later, her WBC count returned to a normal range.

Discussion

According to the Acute Kidney Injury Network (AKIN) [3] and Risk, Injury, Failure, Loss, and End-stage (RIFLE) kidney disease criteria [4], this patient can be diagnosed as stage 3 acute kidney injuries (AKI). We considered it is an acute exacerbation of chronic kidney disease on the basis of her preoperative sCr, fuzzy kidney structure, and the signs of hypocalcemia, hyperphosphatemia and hyperparathyroidism. The potential causes of such acute exacerbation include (1) contrast-induced nephropathy (CIN) after the PCI, (2) application of RAS inhibitors, (3) hypovolemia and prerenal renal failure caused by acute gastrointestinal infections and diarrhea, and (4) rhabdomyolysis caused by statins. AKI affects an estimated 13–18% of inpatients [5,6]. A study shows that the morbidity rate for AKI is 21.6% in adults and 33.7% in children, whereas the mortality rates for adults and children are 23.9% and 13.8%, respectively [5]. The mortality rate is even as high as 60% for elderly patients in the intensive care unit, 80% of whom requires a renal replacement therapy [7]. The most common causes of AKI are infection, renal ischemia, and use of nephrotoxic drugs [8,9]. The risk for AKI is determined by patient-specific factors (e.g. advanced age, chronic kidney disease and other preexisting chronic medical conditions) and other predisposing factors (e.g. sepsis and surgery) [10]. AKI is strongly associated with advanced age, and the recent increase in AKI incidence is linked to the growing size of the elderly population. With the emergence of an aging society and advances in medical care, PCI is widely performed in elderly patients with coronary heart disease to improve their survival rate. Unfortunately, the administration of contrast media (CM) may result in CIN, which is the third most common cause of AKI in patients admitted to hospital [11], subsequently leading to a prolonged hospital stay and increased mortality [12]. According to the European Society of Urogenital Radiology

(ESUR), CIN is defined as an increase of sCr level by more than 44 $\mu\text{mol/L}$ (0.5 mg/dL) or 25% over baseline within 3 days following intravascular CM exposure [13]. In this reported case, the preoperative sCr of this patient was 122 $\mu\text{mol/L}$, and thus, her estimated glomerular filtration rate (eGFR) was 35.4 ml/min/1.73 m^2 according to the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) Study formula. Considering that the decline in renal function was manifested more than 48 h after the use of CM and that the peak of sCr happened over a month after the operation, it is unlikely that the AKI of this patient was caused by CIN. We established rhabdomyolysis as the cause of AKI based on the abnormally high levels of serum myoglobin and CK. Rhabdomyolysis is a clinical syndrome characterized by injury to skeletal muscle fibers with disruption and release of their contents into the circulation. Myoglobin, CK and LDH are the most important substances for indicating muscle damage [14]. The clinical symptoms of rhabdomyolysis are well known: myalgia, weakness and swelling involving injured muscles, usually associated with the presence of myoglobin in urine (i.e. myoglobinuria). The clinical symptoms might include nonspecific symptoms such as fever, nausea, dyspepsia, and vomiting. Mild and subclinical cases of rhabdomyolysis, called in clinical practice myopathies, are typically characterized by elevated serum CK and myalgias [15]. The diagnosis of rhabdomyolysis is primarily based on myoglobinuria or a marked elevation in serum CK [16,17]. Rhabdomyolysis accounts for 13%-50% of AKI cases [18]. Its acquired causes include substance abuse, medication or toxic exposures, electrolyte abnormalities, endocrine disturbances, and autoimmune myopathies. Inherited predisposition to rhabdomyolysis can occur with disorders of glycogen metabolism, fatty acid β -oxidation, and mitochondrial oxidative phosphorylation [16]. The main driver of rhabdomyolysis induced kidney injury is myoglobin, which causes direct damage to renal proximal tubular cells, the formation of casts in distal tubules, renal vasoconstriction, and ischemia. Degradation of reabsorbed myoglobin in the proximal tubular cells leads to the elevation of ionized iron level, development of oxidative stress, and reduction of ATP synthesis. These metabolic changes further result in morphological and functional alterations such as development of acute tubular necrosis, which in concert with ischemia and obstructive damage of distal tubules can form a "vicious circle" [19-21]. Interestingly, this case was atypical because this patient had no definitive muscle pain and swelling. Nevertheless, in view of the tea-colored urine along with the results of laboratory examination, diagnosis can be defined as rhabdomyolysis. Regarding the absence of muscle swelling, hypotension and shock that are commonly associated with rhabdomyolysis, we do not exclude the possibility of a concurrent gastrointestinal tract infection in this patient.

The actual cause of rhabdomyolysis remains elusive. However, since this elderly patient received rosuvastatin for plaque stabilization after PCI, it is possible that her rhabdomyolysis was induced by statin medication. Statins, also known as HMG-CoA reductase inhibitors, are frequently associated with mild muscle complaints. By contrast, their causing of rhabdomyolysis is extremely rare, probably only at a rate of 0.4 per 10,000 person per year [16]. Despite such a low incidence rate, certain drugs

such as amiodarone that this patient has been taking to control ventricular rate could increase the risk of rhabdomyolysis when combined with statins [16]. In fact, a review of the United States Food and Drug Administration post-marketing database of rhabdomyolysis (CK 10,000) showed that, of 866 cases reported between 1987 and 2001, 44% were related to combination therapy, as compared with statins alone [22]. The rosuvastatin specification mention that according to the FDA, the risk of myopathy during rosuvastatin therapy may be increased in Asian Americans because Asians appear to process the drug differently, half the standard dose can have the same cholesterol-lowering benefit in those patients, though a full dose could increase the risk of side-effects, which was indicated by the drug's manufacturer, AstraZeneca. Therefore, physicians should start Asian-American or East Asian patients at the lowest dose level. It also mention that for Asians, the starting dose is 5 mg/d, and for those who need to be more effective in reducing low-density lipoprotein cholesterol (LDL-C) in patients with 10 mg/d can be considered as a starting dose, the dose can control the level of blood lipids in most patients, the maximum dose of this product is 20 mg/d. All statins may be administered to patients with mild to moderate renal insufficiency; all require modified dosing for patients with substantial or severe renal disease [23]. The other study suggested that Rosuvastatin 2.5 mg had superior lipid lowering and cost effectiveness in dyslipidemic patients with concurrent CKD [24]. Moreover, rhabdomyolysis can occur as a result of electrolyte abnormalities (e.g. hypokalemia, hypophosphatemia, hyponatremia, and hypernatremia) in the setting of laxative and diuretic misuse/abuse [25]. Collectively, the combination drug therapy and the presence of concurrent diarrhea and hypokalemia may increase the risk for this patient to develop rhabdomyolysis.

This patient developed serious agranulocytosis 7 days after treatment. Agranulocytosis is a blood dyscrasia characterized by a severe reduction of absolute neutrophil count (ANC) to less than 500 cells/ μl (0.5×10^9 cells/L) in blood. The estimated incidence of agranulocytosis is 1.6 to 7.0 cases per million population per year [26,27]. Most cases of agranulocytosis are drug-induced, and its incidence appears to increase with age, particularly in elderly patients who receive, on average, more drugs than the younger patients [28]. The clinical manifestations of drug-induced agranulocytosis (DIA) include fever, septic shock, pneumonia, sore throat, cutaneous infection, and other infections [29]. The mechanism of DIA has not been fully elucidated; however, two main hypotheses have been proposed [30]. The immune mechanism is based on the presence of antibodies to circulating neutrophils found in the DIA patients, suggesting that an immunological reaction is occurring. Whereas the toxic mechanism proposes that the involvement of reactive metabolites produced by drug metabolism can stimulate a cascade of T cell-mediated reactions primarily against the myeloid cells [30,31]. All classes of medicines have been implicated in agranulocytosis. A systematic review has listed 125 drugs that are definitely or probably responsible for causing agranulocytosis. These drugs include analgesics, anticonvulsants, anti-infectives (including antibiotics, antiviral, and antifungal), antipsychotics, antithyroid drugs, antiplatelet agents, NSAIDs, as well as cardiovascular and gastrointestinal medications [32].

Many anti-infective drugs have been associated with idiosyncratic DIA. A monocentric study showed that antibiotics caused DIA in approximately 25% of the cases, with betalactams and trimethoprim-sulfamethoxazole being the most common rhabdomyolysis inducing antibiotics [33,34].

In our case, the patient, an old lady without a history of blood and autoimmune diseases, developed agranulocytosis after a week of multidrug regimen that includes anti-infective (meropenem), antioxidant (GSH), and volume expansion agent (intralipid, Albumin). Despite only a few reports showing meropenem can cause agranulocytosis, we considered this is the case because her neutrophil count restored to normal when we withdrew meropenem and switched to G-CSF treatment. Thus, special care must be given to patients, especially elderly patients, who receive meropenem and a larger number of drugs at the same time, in order to prevent DIA.

Conclusion

Our case illustrates the importance of being cautious about the potential side effects and drug interactions in elderly people. In our case, both rhabdomyolysis and agranulocytosis are induced by drugs. Although these complications are uncommon, they are potentially fatal. Therefore, we need to pay more attention to the side effects in elderly patients, especially those taking a large number of drugs routinely.
